ABSTRACT

This paper presents a general framework for the design of linear controllers for linear systems subject to time-domain constraints. The design framework exploits sums-of-squares techniques to incorporate the time-domain constraints on closed-loop signals and leads to conditions in terms of linear matrix inequalities (LMIs). This control design framework offers, in addition to constraint satisfaction, also the possibility of including an optimization objective that can be used to minimize steady state (tracking) errors, to decrease the settling time, to reduce overshoot and so on. The effectiveness of the framework is shown via a numerical example.

1. Introduction

The transient response to reference commands or disturbance inputs is an important performance qualifier in many control systems. Unfortunately, most control design strategies cannot cope directly with requirements on time-domain signals such as actuator amplitude or rate limits, no output signal overshoot or undershoot, trajectory planning constraints and so on. Especially in the continuous-time case, there are hardly any systematic controller design methods to enforce time-domain constraints on e.g. tracking errors and control inputs.

In the discrete-time case, model predictive control (MPC) (see e.g. the surveys Garcia, Prett, & Morari, 1989; Mayne, Rawlings, Rao, & Scokaert, 2000; Qin & Badgwell, 2003) is a widely used technique to cope with constraints on inputs and states. In MPC a control action is prescribed that is obtained by solving a finite or infinite horizon optimization problem that can incorporate input, state and output constraints in a direct

manner. A drawback of predictive control concepts and online optimization-based methods in general is that they require a high computational effort with the consequence that they cannot be implemented on fast motion systems where high sampling rates are required, typically in the order of several kHz. Explicit MPC (Bemporad, Heemels, & De Schutter, 2002; Bemporad, Morari, Dua, & Pistikopoulos, 2002; Borrelli, 2003; Tøndel, Johansen, & Bemporad, 2003) might offer an appealing solution as it precomputes a piecewise affine state feedback for discrete-time systems off-line. Still, the explicit control law often leads to a complex description consisting of many affine feedbacks, which also cannot realize the high sampling rates typically needed for motion systems of considerable size, although recent research is focused on decreasing the implementation complexity of MPC; see for instance Grancharova, Johansen, and Tøndel (2005), Grieder, Kvasnica, Baotić, and Morari (2005), Johansen, Jackson, Schreiber, and Tøndel (2006), Kvasnica, Christophersen, Herceg, and Fikar (2008) and Lazar, Heemels, Roset, Nijmeijer, and Bosch (2008) and the references therein. An alternative approach with strong ties to MPC is based on so-called reference governors; see e.g. Bemporad, Casavola, and Mosca (1997) and Gilbert and Kolmanovskiy (2002) and the references therein. A reference governor is a nonlinear device that is added to a primal controller, which functions well in the absence of constraints. The reference governor modifies the reference signal supplied to the primal controller in order to enforce the input and state constraints. This approach suffers from the mentioned drawbacks in MPC to some extent as well, but has

[☆] The material in this paper was partially presented at the 48th IEEE Conference on Decision and Control, December 16–18, 2009, Shanghai, China. This paper was recommended for publication in revised form by Associate Editor Delin Chu under the direction of Editor Ian R. Petersen.

the advantage that the reference modifications are often needed at a lower sampling frequency than the updates of the primal control loop. A major difference with the method presented in this paper is that the overall control systems in case of reference governors become nonlinear devices modifying the supplied reference, while the method in this paper aims at designing *linear* controllers that satisfy the time-domain constraints without any modification of the references or disturbances.

Besides these predictive control methods, that are typically suited for a discrete-time context, there are only a few methods available in the literature that can directly synthesize controllers incorporating time-domain constraints in the continuous-time setting. For instance in the case of input constraints, Goebel and Subbotin (2007) and Heemels, van Eijndhoven, and Stoorvogel (1998) consider the linear quadratic regulator problem with positivity constraints on the input, while various control problems with amplitude and rate constraints on the input signal are solved in Saberi, Stoorvogel, and Sannuti (2000). The latter line of work has also been extended to stabilization and output regulation problems with amplitude and rate constraints on certain output variables, see, e.g., Saberi, Han, and Stoorvogel (2002). Other methods exist that actually allow the control output to saturate such as, for instance, the usage of anti-windup schemes (Franklin, Powell, & Emami-Naeini, 2002; Tarbouriech, Garcia, & Glattfelder, 2007; Tarbouriech & Turner, 2009) or LQR/LQG control methods (Ching, Kabamba, & Meerkov, 2010; Gokcek, Kabamba, & Meerkov, 2001). These methods, however, do not enforce constraint satisfaction but rather guarantee stability or recover performance despite the saturation nonlinearity in the loop. The above mentioned techniques cannot handle *time-varying* constraints, and, except for Saberi et al. (2002), state or output constraints are not considered either. In addition, all the above mentioned techniques result in general in nonlinear controllers.

As already briefly mentioned, in this paper the objective is to derive a design method for *linear* controllers that incorporate possibly *time-varying* time-domain constraints on all closed-loop signals (inputs, states and outputs). Within this context, a commonly used method to capture the essence of time-domain specifications is the reformulation into frequency domain requirements (Doyle, Francis, & Tannenbaum, 1992). Unfortunately, such reformulations are in general either approximate, conservative or both.

A methodology to enforce time-domain constraints on the input and output of a continuous-time linear control system is presented recently in Henrion, Tarbouriech, and Kučera (2005), where linear matrix inequality (LMI) techniques are used to synthesize a fixed order linear controller that satisfies the constraints. This is done in a polynomial setting in the sense that a controller is designed according to the well-known pole placement method using the Diophantine equation. This method allows the design of a controller that results in a closed-loop transfer function with prescribed pole locations, either exact, or within an admissible region of the complex plane. In Henrion et al. (2005), all controllers with the prescribed pole locations are characterized using the Youla–Kučera parametrization (Kučera, 1994). Next the degrees of freedom of the Youla–Kučera parametrization are used to enforce certain time-domain constraints, such as bounds on the input amplitude and output overshoot, exploiting sums-of-squares techniques. Unfortunately, the approach in Henrion et al. (2005) is limited to the assignment of distinct strictly negative *real* closed-loop poles, which is a severe restriction in the case of many practical situations such as, for instance, lightly damped systems. As a consequence, there is a strong need for a general framework encompassing arbitrary closed-loop pole placement. The development of such a framework is the main purpose of this paper.

In particular, we propose an extension to the method in Henrion et al. (2005), which leads to a general design framework based

on sums-of-squares LMI techniques and we show indeed that the resulting linear controller satisfies the time-domain constraints on closed-loop signals, even when complex conjugate poles are assigned. This framework is based on two relaxations. One of these relaxations, of which a preliminary version was presented by the authors in Aangenent, Heemels, van de Molengraft, and Steinbuch (2009), can solve the constrained control problem at hand with arbitrary accuracy and still lead to LMIs. In addition to constraint satisfaction, we will also include an objective function in the convex programming problem that can be used to minimize steady state (tracking) errors, to decrease the settling time, to reduce the overshoot and so on. As a consequence, the ideas presented in this paper will lead to a general design framework for optimized linear controllers with guarantees regarding constraint satisfaction.

The organization of the paper is as follows. The proposed methodology from Henrion et al. (2005) is briefly reviewed in Section 2. The extension to complex conjugate poles is treated in Section 3, which includes the main results. Section 4 discusses the proposed control design method, and Section 5 provides an illustrative example. Finally, the conclusions are stated in Section 6.

2. Methodology involving real poles

In Henrion et al. (2005) a method is presented to incorporate time-domain constraints on input and output signals of a linear system. It is shown that finding a controller of fixed order that satisfies these constraints boils down to solving a set of LMIs. In this section, we shortly review this procedure for completeness and self-containedness.

2.1. Youla–Kučera parametrization

Consider the control system depicted in Fig. 1 with a linear single-input–single-output plant P given by the strictly proper transfer function

$$P(s) = \frac{b(s)}{a(s)}, \quad (1)$$

where $a(s)$ and $b(s)$ are polynomials in the Laplace variable s . The controller C , which is to be designed, is described accordingly by

$$C(s) = \frac{d(s)}{c(s)}, \quad (2)$$

resulting in the complementary sensitivity given by

$$T(s) = \frac{y(s)}{r(s)} = \frac{b(s)d(s)}{a(s)c(s) + b(s)d(s)}. \quad (3)$$

If $a(s)$ and $b(s)$ are coprime (i.e., their greatest common divisor is 1), then arbitrary pole placement can be achieved by designing the corresponding controller polynomials. This is done by solving the polynomial Diophantine equation

$$a(s)c(s) + b(s)d(s) = z(s), \quad (4)$$

where $z(s) = (s + p_1)(s + p_2) \dots (s + p_n)$ is the polynomial with given roots $-p_1, \dots, -p_n$, which are the desired poles of the closed-loop system. There are infinitely many solutions $(c(s), d(s))$ to (4), but there is a unique solution pair $(c_0(s), d_0(s))$ such that $\deg d_0(s) < \deg a(s)$. In this case we have that $d_0(s)$ is of minimal degree and as such, $(c_0(s), d_0(s))$ is called the d -minimal solution pair. All possible solutions to the Diophantine equation can then be written as

$$\begin{aligned} c(s) &= c_0(s) + b(s)q(s), \\ d(s) &= d_0(s) - a(s)q(s), \end{aligned} \quad (5)$$

where $q(s)$ is an arbitrary polynomial such that $c_0(s) + b(s)q(s)$ is non-zero. This polynomial, called the Youla–Kučera parameter

Fig. 1. Block diagram of the closed-loop system with controller C , plant P , and reference signal r , control output signal u , and output signal y .

(Francis, 1987), creates extra freedom in the design of the controller. While the closed-loop poles are invariant for any choice of the Youla–Kučera parameter, the Youla–Kučera parameter enables placement of closed-loop zeros to alter the response. Only proper controllers are considered and therefore there is a degree constraint on $q(s)$. Since the plant was assumed to be strictly proper, and under the additional assumption that $\deg z(s) \geq 2 \deg a(s) - 1$ (to enable arbitrary pole placement with proper controllers), this constraint is given as in Kučera and Zagalak (1999) by

$$\deg q(s) \leq \deg z(s) - 2 \deg a(s). \quad (6)$$

The extra freedom in the control design parameterized by $q(s)$ satisfying (6) can now be used to satisfy additional time-domain constraints as will be explained in the next section.

2.2. A positive polynomial formulation of time-domain constraints

We will explain the procedure in Henrion et al. (2005) using the typical example of constraints on the step response. Hence, we consider the response y to a step input ($r(s) = \frac{1}{s}$). The Laplace transform of the closed-loop system's output (assuming zero initial conditions) is then given by

$$y(s) = \frac{1}{s} \frac{b(s)d(s)}{z(s)} = \frac{1}{s} \frac{b(s)d_0(s)}{z(s)} - \frac{1}{s} \frac{a(s)b(s)}{z(s)} q(s). \quad (7)$$

At this point of the control design a restrictive assumption was made (Henrion et al., 2005), namely

Assumption 2.1. All the assigned poles $-p_1, \dots, -p_n$ are distinct strictly negative rational numbers.

Using this assumption and $z(s) = \prod_{i=1}^n (s+p_i)$ the partial fractional decomposition of (7) leads to

$$y(s, q) = \sum_{i=0}^n \frac{y_i(q)}{s+p_i}, \quad (8)$$

where $p_0 = 0$ and $y_i(q)$, $i = 1, \dots, n$ are appropriate coefficients following from the decomposition, which are influenced by the choice of the design parameter $q(s) = \sum_{i=0}^{d_q} q_i s^i$. The coefficients $y_i(q)$ depend in an affine manner on the parameter $q = (q_0, q_1, \dots, q_{d_q})$ in the sense that there exist matrices $A \in \mathbb{R}^{(n+1) \times (n+1)}$, $B \in \mathbb{R}^{(n+1) \times (q_d)}$ and a vector $b \in \mathbb{R}^{n+1}$ such that

$$A \begin{pmatrix} y_0(q) \\ y_1(q) \\ \vdots \\ y_{n+1}(q) \end{pmatrix} = Bq^T + b. \quad (9)$$

This follows directly by comparing (7) and (8), and equating the coefficients of the powers of s in the resulting numerator polynomials (see also (46) below for an example). The corresponding time-domain signal is given by

$$y(t, q) = \sum_{i=0}^n y_i(q) e^{-p_i t}. \quad (10)$$

Let $p_i = \frac{n_i}{d_i}$ be the ratios of the integers n_i and d_i , and let m denote the smallest positive number¹ of the denominators such that $p_i = \frac{\bar{p}_i}{m}$ for some positive integers \bar{p}_i , $i = 0, 1, \dots, n$. This means that the time-domain output signal at time $t \in \mathbb{R}_+ := [0, \infty)$ can now be expressed as the polynomial

$$y(\lambda, q) = \sum_{i=0}^n y_i(q) \lambda^{\bar{p}_i} \quad (11)$$

in the indeterminate $\lambda = e^{-t/m}$. Obviously, λ lies in the interval $[0, 1]$ as $t \in \mathbb{R}_+$. Suppose that the output $y(t, q)$ of the system needs to be bounded according to

$$y_{\min} \leq y(t, q) \leq y_{\max} \quad \forall t \in \mathbb{R}_+. \quad (12)$$

Formulation (12) is equivalent to enforcing the polynomial bound constraints

$$\begin{cases} P_1(q, \lambda) := y(\lambda, q) - y_{\min} \geq 0 \\ P_2(q, \lambda) := y_{\max} - y(\lambda, q) \geq 0 \end{cases} \quad \forall \lambda \in [0, 1], \quad (13)$$

where P_1 and P_2 are polynomials in both λ and q . This problem is a special case of the following more general problem of minimizing a polynomial with polynomial constraints over a basic semialgebraic set.

Definition 2.1. A set \mathcal{D} is called a basic semialgebraic set if it can be described as

$$\mathcal{D} = \{x \in \mathbb{R}^n \mid e_i(x) \geq 0, i = 1, \dots, M_e \text{ and } f_j(x) = 0, j = 1, \dots, M_f\} \quad (14)$$

for certain polynomials $e_i : \mathbb{R}^n \rightarrow \mathbb{R}$, $i = 1, \dots, M_e$ and $f_j : \mathbb{R}^n \rightarrow \mathbb{R}$, $j = 1, \dots, M_f$.

Problem 2.1 (Polynomial Optimization Problem). Consider two variables $z \in \mathbb{R}^{n_z}$ and $x \in \mathbb{R}^{n_x}$ and let polynomials $g_i : \mathbb{R}^{n_z} \times \mathbb{R}^{n_x} \rightarrow \mathbb{R}$, $i = 1, \dots, M_g$, and $p : \mathbb{R}^{n_z} \rightarrow \mathbb{R}$ be given. Moreover, let a collection of basic semialgebraic sets $\mathcal{D}_l \subseteq \mathbb{R}^{n_x}$, $l = 0, \dots, N$ be given. A (robust) polynomial optimization problem according to this data is given by

$$\begin{aligned} \min_z \quad & p(z) \\ \text{s.t.} \quad & g_i(z, x) \geq 0, \quad i = 1, \dots, M_g \quad \forall x \in \bigcup_{l=0}^N \mathcal{D}_l. \end{aligned} \quad (15)$$

Indeed, (13) can now be written in the form of Problem 2.1 by taking $z = q$, $x = \lambda$, $M_g = 2$, $N = 0$, $p(z) = 0$, $g_1(z, x) = P_1(q, \lambda)$, $g_2(z, x) = P_2(q, \lambda)$, and $\mathcal{D}_0 = \{\lambda \in \mathbb{R} \mid 0 \leq \lambda \leq 1\}$. Although the bounds y_{\min} and y_{\max} in (13) are chosen to be constants for illustrating purposes, they can also be selected as polynomials in λ , i.e., in the form $y_{\min}(\lambda)$ and $y_{\max}(\lambda)$ without any complications. In this case the bounds in (12) become time-varying. Univariate positive polynomial constraints (meaning polynomials in only one variable), such as (13) with $\lambda \in \mathcal{D}_0 = [0, 1] \subseteq \mathbb{R}$, can be transformed into LMI conditions, see Henrion et al. (2005) for the details. Once we transformed the design problem into a polynomial optimization problem as formulated in Problem 2.1, there are appropriate tools available for solving the problem. Therefore, we restrict ourselves to the transformation of the constrained control problems at hand into manifestations of Problem 2.1.

¹ In principle m can be chosen to be any positive number that results in integer values of \bar{p}_i . However, it turns out that by choosing m as the smallest possible positive number the order of the resulting polynomial optimization problem is the lowest.

The approach discussed in this section is not restricted to bounding only the output of a system. Indeed, by using the appropriate transfer functions, any signal in the loop can be constrained. The control output u , for example, can be bounded using

$$u(s) = r(s) \frac{a(s)d_0(s)}{z(s)} - r(s) \frac{a^2(s)}{z(s)} q(s) \quad (16)$$

in addition to, or instead of (7). Also, other Laplace transformable inputs or disturbances can be used as long as the poles of the Laplace transform of the corresponding signal are distinct strictly negative rational numbers and differ from the closed-loop poles p_i . In case the disturbance signal is a (filtered) random process, the method cannot be applied as is. However, a possible extension can be to bound the infinity- or 2-norm of the suitably weighted process sensitivity (or other relevant transfer functions) via e.g.

$$\left\| V(s) \frac{b(s)c(s)}{a(s)c(s) + b(s)d(s)} W(s) \right\|_{2/\infty} \leq 1. \quad (17)$$

This way the knowledge of stochastic disturbances can be used to shape the relevant sensitivity functions to achieve desired disturbance reduction.

A combination of requirements on different reference signals can easily be handled at the cost of increasing the size of the set of LMIs. As for LMIs there are efficient solvers available, e.g. [Sturm \(1999\)](#), transforming the problem at hand into [Problem 2.1](#) provides an effective solution. The problem derived in this section was only a feasibility problem (the cost criterion $p(z)$ was chosen to be 0). In [Section 4](#), we will also provide relevant choices for the cost criterion that next to satisfaction of the time-domain constraints also provides additional desirable properties of the constructed controller.

3. Problem formulation: the complex pole case

The polynomial representation (10), as derived in [Henrion et al. \(2005\)](#), of the time response of a linear system to a Laplace transformable input is unfortunately only possible when strictly negative rational closed-loop poles are assigned (see [Assumption 2.1](#)). However, in many cases the assignment of purely real poles can be undesirable, especially in lightly damped systems such as most motion systems. Furthermore, many reference signals have Laplace transforms with complex poles. If, for instance, a sinusoid is used as the reference signal instead of a step, the Laplace transform is given by $r(s) = \frac{\omega}{s^2 + \omega^2}$ resulting in complex poles in the system's response. Therefore, such reference signals cannot be handled by the approach from [Henrion et al. \(2005\)](#). The main objective of this paper is to present a solution to the linear control design problem for time-domain constrained systems of which the Laplace transforms of the closed-loop responses may contain complex roots.

When we allow both distinct real and complex poles to be present in the closed-loop transfer function $T(s)$ and/or the Laplace transform of the reference signal $r(s)$, the Laplace transform of the system's output can be decomposed as the partial fractional decomposition

$$y(s) = \sum_{i=0}^{n_r} \frac{y_i}{s + p_i} + \sum_{i=n_r+1}^{n_r+n_c/2+1} \frac{y_i}{s + \alpha_i + j\beta_i} + \frac{y_i^*}{s + \alpha_i - j\beta_i}, \quad (18)$$

where n_r and n_c denote the number of real and complex poles, respectively, $-p_i, i = 1, \dots, n_r$ are the locations of the real poles, $-\alpha_i \pm j\beta_i, i = n_r + n_c/2 + 1$ are the locations of complex conjugate pairs of poles, and y_i are the possibly complex coefficients (with complex conjugate y_i^*) that affinely depend on

the design parameter q , see (9) (we omitted this dependence on q for ease of exposition). To enforce stability, we again assume that the assigned closed-loop poles have strictly negative real part. The corresponding time-domain signal is then described by

$$y(t) = \sum_{i=0}^{n_r} y_i e^{-p_i t} + \sum_{i=n_r+1}^{n_r+n_c/2+1} (y_i e^{-j\beta_i t} + y_i^* e^{j\beta_i t}) e^{-\alpha_i t}. \quad (19)$$

As before, we use the following assumption

Assumption 3.1. p_i, α_i , and β_i are rational numbers.

We denote $p_i = \frac{\bar{p}_i}{m}, \alpha_i = \frac{\bar{\alpha}_i}{m}, \tau = \frac{t}{m}$ where m is the smallest positive number (not necessarily an integer) of p_i and α_i such that \bar{p}_i and $\bar{\alpha}_i$ can be taken as integers. We denote $\beta_i = \frac{\theta \bar{\beta}_i}{m}$ for a number θ (not necessarily an integer) such that $\bar{\beta}_i$ can be taken as integer as well. For guidelines how to choose θ , see [Remark 3.1](#) below. Furthermore, let

$$\lambda = e^{-\tau}. \quad (20)$$

Using Euler's formula $e^{j\phi} = \cos(\phi) + j \sin(\phi)$ and decomposing the complex coefficients as $y_i = a_i + j b_i, y_i^* = a_i - j b_i$, yields

$$y(t) = \sum_{i=0}^{n_r} y_i \lambda^{\bar{p}_i} + \sum_{i=n_r+1}^{n_r+n_c/2+1} (a_i 2 \cos(\bar{\beta}_i \theta \tau) + b_i 2 \sin(\bar{\beta}_i \theta \tau)) \lambda^{\bar{\alpha}_i}. \quad (21)$$

Obviously, the terms involving the complex poles are non-polynomial in the indeterminate λ because of the presence of $\cos(\bar{\beta}_i \theta \tau)$ and $\sin(\bar{\beta}_i \theta \tau)$, which make it impossible to directly use the positive polynomial approach in [Section 2](#) to bound the output as in (12). Although the parameters $\bar{\alpha}_i, \bar{\beta}_i$ and \bar{p}_i are fixed as a result of the pole placement (and the choice of m and θ), there still is freedom in the choice for the coefficients a_i, b_i , which depend on the coefficients $q = (q_0, \dots, q_{d_q})$ in the Youla-Kučera parameter $q(s)$. We propose two relaxations to determine the values y_i, a_i, b_i via polynomial optimization problems to shape the time response $y(t)$, thereby overcoming the limitations in [Henrion et al. \(2005\)](#). The first approach is based on an exponential bound relaxation that results in univariate polynomials. This method has the advantage that it results in a simple polynomial optimization problem, but introduces some conservatism. The second method proposes a multivariate polynomial relaxation that leads to polynomial problems as in [Problem 2.1](#), while the conservatism can be made arbitrarily small. Both methods result in polynomial optimization problems of the type as in [Problem 2.1](#) that can be solved using LMIs.

3.1. Exponential bound relaxation

To resolve the problem induced by the presence of the products $\cos(\bar{\beta}_i \theta \tau) \lambda^{\bar{\alpha}_i}$ and $\sin(\bar{\beta}_i \theta \tau) \lambda^{\bar{\alpha}_i}$ in (21) we relax the problem by using the fact that

$$\cos(\bar{\beta}_i \theta \tau), \quad \sin(\bar{\beta}_i \theta \tau) \in [-1, 1] \quad \forall \tau \in \mathbb{R}, \quad (22)$$

and instead of the exact time-response (21), we consider

$$y_{\text{upper}}(\lambda) = \sum_{i=0}^{n_r} y_i \lambda^{\bar{p}_i} + \sum_{i=n_r+1}^{n_r+n_c/2+1} (2|a_i| + 2|b_i|) \lambda^{\bar{\alpha}_i}, \quad (23)$$

$$y_{\text{lower}}(\lambda) = \sum_{i=0}^{n_r} y_i \lambda^{\bar{p}_i} - \sum_{i=n_r+1}^{n_r+n_c/2+1} (2|a_i| + 2|b_i|) \lambda^{\bar{\alpha}_i}.$$

In contrast to (21), these exponential bounds on the closed-loop time response are univariate polynomials in the indeterminate $\lambda = e^{-\tau}$ (if q is fixed) and can be bounded by specified polynomials $g_u(\lambda)$ and $g_l(\lambda)$ via the polynomial non-negativity constraints

$$\begin{aligned} P_3(q, \lambda) &:= g_u(\lambda) - y_{\text{upper}}(\lambda) \geq 0 \\ P_4(q, \lambda) &:= y_{\text{lower}}(\lambda) - g_l(\lambda) \geq 0 \quad \forall \lambda \in [0, 1], \end{aligned} \quad (24)$$

where we included the explicit dependence of y_i , a_i and b_i on q again. The constraints (24) cannot straightforwardly be cast in the form Problem 2.1 because of the nonlinear operator $|\cdot|$, which is present in these equations. However, each of the two nonlinear inequality constraints P_3 and P_4 can be expressed as 2^{n_c+1} equivalent polynomial inequality constraints \tilde{P}_3 and \tilde{P}_4 (2 inequalities for each absolute value expression). Enforcing non-negativity of (24) on the interval $\lambda \in [0, 1]$ is then again a special case of Problem 2.1 with $z = q$, $x = \lambda$, $M_g = 2$, $M_h = 0$, $N = 0$, $p(z, x) = 0$, $g_1(z, x) = \tilde{P}_3(q, \lambda)$, $g_2(z, x) = \tilde{P}_4(q, \lambda)$, and $\mathcal{D}_0 = \{\lambda \in \mathbb{R} \mid 0 \leq \lambda \leq 1\}$. Therefore, it is possible to determine the values $q = (q_0, \dots, q_{d_q})$ such that the upper and lower bounds (23) of the closed-loop time response are bounded by $g_u(\lambda)$ (e.g. $g_u(\lambda) = y_{\text{max}}$) and $g_l(\lambda)$ (e.g. $g_l(\lambda) = y_{\text{min}}$) via a polynomial optimization problem. The exponential bound relaxation does introduce some conservatism by using relaxation (23) instead of the exact time-response (21). The second method presented next offers the possibility to render this conservatism arbitrary small. In other words, the second method can approximate the original time-domain constraints with arbitrary accuracy and still lead to polynomial optimization problems.

3.2. Multivariate polynomial relaxation

The time response (21) is equivalent to

$$\begin{aligned} y(t) &= \sum_{i=0}^{n_r} y_i \lambda^{\bar{p}_i} \\ &+ \sum_{i=n_r+1}^{n_r+n_c/2+1} [(a_i + jb_i) (\cos(\bar{\beta}_i \theta \tau) - j \sin(\bar{\beta}_i \theta \tau)) \\ &+ (a_i - jb_i) (\cos(\bar{\beta}_i \theta \tau) + j \sin(\bar{\beta}_i \theta \tau))] \lambda^{\bar{\alpha}_i}. \end{aligned} \quad (25)$$

De Moivre's formula, which is closely related to Euler's formula and $(e^{j\phi})^n = e^{jn\phi}$, states that for any $\phi \in \mathbb{R}$ and any integer $n \in \mathbb{Z}$

$$(\cos(\phi) + j \sin(\phi))^n = \cos(n\phi) + j \sin(n\phi), \quad (26)$$

and hence (25) is equal to

$$\begin{aligned} y(t) &= \sum_{i=0}^{n_r} y_i \lambda^{\bar{p}_i} \\ &+ \sum_{i=n_r+1}^{n_r+n_c/2+1} ((a_i + jb_i) [\cos(\theta \tau) - j \sin(\theta \tau)]^{\bar{\beta}_i} \\ &+ (a_i - jb_i) [\cos(\theta \tau) + j \sin(\theta \tau)]^{\bar{\beta}_i}) \lambda^{\bar{\alpha}_i}. \end{aligned} \quad (27)$$

Appropriate polynomial functions $w_i : \mathbb{R}^2 \rightarrow \mathbb{R}$ and $r_i : \mathbb{R}^2 \rightarrow \mathbb{R}$, $i = n_r + 1, \dots, n_r + n_c/2 + 1$ in two variables can now be defined such that (27), and thus the time response (21), can be written as

$$\begin{aligned} y(t) &= \sum_{i=0}^{n_r} y_i \lambda^{\bar{p}_i} + \sum_{i=n_r+1}^{n_r+n_c/2+1} (a_i 2w_i(\cos(\theta \tau), \sin(\theta \tau)) \\ &+ b_i 2r_i(\cos(\theta \tau), \sin(\theta \tau))) \lambda^{\bar{\alpha}_i}. \end{aligned} \quad (28)$$

This proves the following theorem.

Theorem 3.1. Consider the closed-loop system (3) and let y be the response to a reference input r and assume that the Laplace transform $y(s)$ of y has only distinct poles such that (18) and Assumption 3.1 hold. Then we have that

$$\{y(t) \mid t \in \mathbb{R}^+\} = \{y(u, v, \lambda) \mid (u, v, \lambda) \in \mathcal{F}_{\text{original}}\}, \quad (29)$$

where $y(u, v, \lambda)$ is given by the multivariate polynomial

$$\begin{aligned} y(u, v, \lambda) &= \sum_{i=0}^{n_r} y_i \lambda^{\bar{p}_i} \\ &+ \sum_{i=n_r+1}^{n_r+n_c/2+1} (a_i 2w_i(u, v) + b_i 2r_i(u, v)) \lambda^{\bar{\alpha}_i} \end{aligned} \quad (30)$$

with $w_i : \mathbb{R}^2 \rightarrow \mathbb{R}$ and $r_i : \mathbb{R}^2 \rightarrow \mathbb{R}$, $i = n_r + 1, \dots, n_r + n_c/2 + 1$ polynomials as in (28) and

$$\begin{aligned} \mathcal{F}_{\text{original}} &:= \{(u, v, \lambda) \in \mathbb{R}^3 \mid u = \cos(\theta \tau), v = \sin(\theta \tau), \\ &\lambda = e^{-\tau} \text{ for some } \tau \in \mathbb{R}^+\}. \end{aligned} \quad (31)$$

Proof. The reasoning before the formulation of the theorem revealed that $y(t)$ under the given assumptions is equal to (19), which can equivalently be written as (28), where $\lambda = e^{-\tau}$ and $\tau = \frac{t}{m}$. \square

Due to Theorem 3.1, bounding the output as in (12) to the interval $[y_{\text{min}}, y_{\text{max}}]$ is equivalent to enforcing the polynomial non-negativity constraints

$$\begin{aligned} P_5(q, u, v, \lambda) &:= y(u, v, \lambda) - y_{\text{min}} \geq 0, \\ P_6(q, u, v, \lambda) &:= y_{\text{max}} - y(u, v, \lambda) \geq 0 \end{aligned} \quad (32)$$

for all $(u, v, \lambda) \in \mathcal{F}_{\text{original}}$. Recall that $y(u, v, \lambda)$ depends on q via y_i , a_i and b_i . As we mentioned before, it is of interest to transform the linear constrained control problem into Problem 2.1. The conditions (32) are not in this form due to the fact that $\mathcal{F}_{\text{original}}$ is not a (finite union of) basic semialgebraic set(s) as in Definition 2.1. However, this set can be overapproximated by a finite union of basic semialgebraic sets in an arbitrarily close manner.

Definition 3.1. We call a set $\mathcal{F}_{\text{approx}}$ an ε -close overapproximation of $\mathcal{F}_{\text{original}}$ for some $\varepsilon > 0$, if it satisfies the following three properties:

- (1) $\mathcal{F}_{\text{approx}} = \bigcup_{l=0}^N \mathcal{F}_l$ for a finite collection of basic semialgebraic sets $\mathcal{F}_0, \dots, \mathcal{F}_N$;
- (2) $\mathcal{F}_{\text{original}} \subseteq \mathcal{F}_{\text{approx}}$;
- (3) $\mathcal{F}_{\text{approx}} \subseteq \mathcal{F}_{\text{original}} + \mathbb{B}_\varepsilon$, where $\mathbb{B}_\varepsilon := \{(0, 0, z) \mid -\varepsilon \leq z \leq \varepsilon\}$.

Hence, an ε -close overapproximation of $\mathcal{F}_{\text{original}}$ contains the set $\mathcal{F}_{\text{original}}$ as drawn by the white line in Fig. 2 (for $\theta = 1$), but it is ε -close in the sense of property (3). Hence, for small $\varepsilon > 0$, replacing $\mathcal{F}_{\text{original}}$ by $\mathcal{F}_{\text{approx}}$ only results in small errors and all guarantees on $\mathcal{F}_{\text{approx}}$ also apply to $\mathcal{F}_{\text{original}}$ due to property (2). Moreover, due to property 1 an ε -close overapproximation $\mathcal{F}_{\text{approx}}$ of $\mathcal{F}_{\text{original}}$ can be used to embed the polynomial constraints in (32) for all $(u, v, \lambda) \in \mathcal{F}_{\text{original}}$ into a version of the constraints in Problem 2.1, where $\mathcal{D}_l = \mathcal{F}_l$, $l = 0, \dots, N$.

The following algorithm provides an algorithm that constructs for each desirable level of approximation ε an ε -close overapproximation of $\mathcal{F}_{\text{original}}$. The basic idea of the algorithm is to overapproximate the $\mathcal{F}_{\text{original}}$ -set by the union of basic semialgebraic sets \mathcal{F}_l , which are obtained by splitting the set $\mathcal{F}_{\text{original}}$ in the τ -direction by considering intervals $I_l := [\tau_l, \tau_{l+1})$, $l = 0, \dots, N$, where $0 = \tau_0 < \tau_1 < \dots < \tau_{N+1} = \infty$. On each of these subintervals I_l we approximate $e^{-\tau}$ by $\psi_l(\cos(\theta \tau), \sin(\theta \tau))$ using Fourier series, where $\psi_l : \mathbb{R}^2 \rightarrow \mathbb{R}$ is a polynomial such that

Fig. 2. $\mathcal{F}_{\text{original}}$ (white line) drawn inside the cylinder given by $u^2 + v^2 = 1$ and $0 \leq \lambda \leq 1$.

$|e^{-\tau} - \psi_l(\cos(\theta\tau), \sin(\theta\tau))| \leq \varepsilon$ for all $\tau \in I_l$. Next to ε , the algorithm uses another parameter $0 < T < \frac{2\pi}{\theta}$, which indicates the desired length of the intervals $I_l, l = 0, \dots, N - 1$ (although it will be modified such that all intervals have the same length).

Algorithm 1. Let $0 < \varepsilon < 1$ and $0 < T < \frac{2\pi}{\theta}$ be given.

Step 1: Define $N := \lceil \frac{-\ln \varepsilon}{T} \rceil$ and $\tau_N := -\ln \varepsilon$ and $\tau_{N+1} := \infty$.

$$\mathcal{F}_N := \{(u, v, \lambda) \in \mathbb{R}^3 \mid u^2 + v^2 = 1 \text{ and } 0 \leq \lambda \leq \varepsilon\}. \quad (33)$$

Step 2: Divide the remaining interval $[0, \tau_N]$ in N subintervals of length $\bar{T} := \frac{\tau_N}{N} \leq T < \frac{2\pi}{\theta}$. $I_l := [\tau_l, \tau_{l+1})$ with $\tau_l = l\bar{T}, l = 0, \dots, N - 1$.

Step 3: For each $l = 0, \dots, N - 1$ define a function $\phi_l : \mathbb{R} \rightarrow \mathbb{R}$ that satisfies:

- ϕ_l is at least continuously differentiable, but preferably m times continuously differentiable (C^m) for $m \in \mathbb{N}$ large;
- ϕ_l is periodic with period $\frac{2\pi}{\theta}$;
- $\phi_l(\tau) = e^{-\tau}$ for all $\tau \in I_l$.

Step 4: For each $l = 0, \dots, N - 1$ compute the Fourier series approximation of ϕ_l of sufficiently high degree K_l such that

$$|\phi_l(\tau) - \sum_{k=0}^{K_l} [a_k \cos(k\theta\tau) + b_k \sin(k\theta\tau)]| \leq \varepsilon$$

for all $\tau \in I_l$, (34)

where $a_k, b_k, k = 0, \dots, K_l$ are the Fourier coefficients of ϕ_l .

Step 5: For each $l = 0, \dots, N - 1$ use De Moivre's formula to rewrite $\sum_{k=0}^{K_l} [a_k \cos(k\theta\tau) + b_k \sin(k\theta\tau)]$ obtained in the previous step as

$$\sum_{k=0}^{K_l} \sum_{i=0}^k c_{ki} (\cos(\theta\tau))^k (\sin(\theta\tau))^i =: \psi_l(\cos(\theta\tau), \sin(\theta\tau)),$$

where $\psi_l : \mathbb{R}^2 \rightarrow \mathbb{R}$ is a polynomial of degree equal to the degree of the Fourier series.

Step 6: For each $l = 0, \dots, N - 1$, define

$$\mathcal{F}_l := \{(u, v, \lambda) \in \mathbb{R}^3 \mid -\varepsilon \leq \lambda - \psi_l(u, v) \leq \varepsilon \wedge u^2 + v^2 = 1 \wedge (S_l - S_{l+1})u + (C_{l+1} - C_l)v + S_{l+1}C_l - C_{l+1}S_l \leq 0\}, \quad (35)$$

where $C_l := \cos(\theta\tau_l), S_l := \sin(\theta\tau_l)$.

Step 7: Take $\mathcal{F}_{\text{approx}} = \bigcup_{l=0}^N \mathcal{F}_l$.

Theorem 3.2. For each $0 < \varepsilon < 1$ and $0 < T < \frac{2\pi}{\theta}$ Algorithm 1 produces an ε -close overapproximation $\mathcal{F}_{\text{approx}}$ of $\mathcal{F}_{\text{original}}$ in the sense of Definition 3.1.

Fig. 3. Top-view of the cylinder $\{(u, v, \lambda) \in \mathbb{R}^3 \mid u^2 + v^2 = 1, 0 \leq \lambda \leq 1\}$ (solid grey), the hyperplane $\{(u, v, \lambda) \in \mathbb{R}^3 \mid (36)\}$ (dashed), and the resulting part of the cylinder given by $\{(u, v, \lambda) \in \mathbb{R}^3 \mid u^2 + v^2 = 1, (37), 0 \leq \lambda \leq 1\}$ (solid black).

Proof. First of all, we write $\mathcal{F}_{\text{original}}$ as $\bigcup_{l=0}^N \mathcal{F}_{\text{original},l}$ with $\mathcal{F}_{\text{original},l} := \{(\cos \theta\tau, \sin \theta\tau, e^{-\tau}) \mid \tau \in I_l\}$ for $l = 0, 1, \dots, N$ as $\bigcup_{l=0}^N I_l = [0, \infty)$. Step 1 considers the interval $I_N := [\tau_N, \tau_{N+1}) = [-\ln \varepsilon, \infty)$ for which it holds that $0 \leq e^{-\tau} \leq \varepsilon$. Hence, clearly $\mathcal{F}_{\text{original},N} \subseteq \mathcal{F}_N$ and $\mathcal{F}_N \subseteq \mathcal{F}_{\text{original},N} + \mathbb{B}_\varepsilon$. The construction of functions ϕ_l in step 3 is possible as $e^{-\tau}$ is continuous and the fact that $0 < \bar{T} \leq T < \frac{2\pi}{\theta}$. Hence, step 3 can always be taken, while the function ϕ_l can still be made $\frac{2\pi}{\theta}$ -periodic and continuously differentiable. Step 4 can be realized, because the Fourier series converges uniformly to a continuously differentiable periodic function, see, e.g., Asmar (2005) and Powers (2006). Therefore, uniform convergence proves the existence of a finite K_l such that (34) holds. Note now that for $(u, v, \lambda) \in \mathcal{F}_{\text{original},l}$ it holds that $u^2 + v^2 = 1$. Obviously, $(\cos(\theta\tau), \sin(\theta\tau))$ for $\tau \in I_l = [\tau_l, \tau_{l+1})$ lies in one of the half spaces generated by the straight line in \mathbb{R}^2 through the points $(\cos(\theta\tau_l), \sin(\theta\tau_l))$ and $(\cos(\theta\tau_{l+1}), \sin(\theta\tau_{l+1}))$ given by

$$\begin{aligned} & [\sin(\theta\tau_l) - \sin(\theta\tau_{l+1})] \underbrace{\cos(\theta\tau)}_u \\ & + [\cos(\theta\tau_{l+1}) - \cos(\theta\tau_l)] \underbrace{\sin(\theta\tau)}_v \\ & + \sin(\theta\tau_{l+1}) \cos(\theta\tau_l) - \cos(\theta\tau_{l+1}) \sin(\theta\tau_l) = 0, \end{aligned} \quad (36)$$

see Fig. 3. In particular, for all $(u, v, \lambda) \in \mathcal{F}_{\text{original},l}$ it holds that

$$(S_l - S_{l+1})u + (C_{l+1} - C_l)v + S_{l+1}C_l - C_{l+1}S_l \leq 0 \quad (37)$$

where $C_l := \cos(\theta\tau_l), S_l := \sin(\theta\tau_l)$. Due to (34), step 5, and using the above observations, it holds that $\mathcal{F}_{\text{original},l} \subseteq \mathcal{F}_l$. Moreover, similar reasoning using (34) shows that $\mathcal{F}_l \subseteq \mathcal{F}_{\text{original},l} + \mathbb{B}_\varepsilon$. Hence, by taking $\mathcal{F}_{\text{approx}}$ as the union of the resulting sets, i.e. $\mathcal{F}_{\text{approx}} = \bigcup_{l=0}^N \mathcal{F}_l$, an ε -close overapproximation $\mathcal{F}_{\text{approx}}$ of $\mathcal{F}_{\text{original}}$ is obtained. This completes the proof. \square

For instance, for $\theta = 1, \varepsilon = e^{-1.5\pi} \approx 0.009$ and $T = \bar{T} = 0.75\pi$ the ε -close overapproximation $\mathcal{F}_{\text{approx}}$ of $\mathcal{F}_{\text{original}}$ can be generated with $\tau_0 = 0, \tau_1 = 0.75\pi, \tau_2 = 1.5\pi$ and $\tau_3 = \infty$ and polynomials

$$\begin{aligned} \psi_0(u, v) &= 0.398u - 0.971v + 0.616u^2 - 0.192uv + 1.179v^2 \\ &\quad - 0.015u^3 + 0.184u^2v, \\ \psi_1(u, v) &= 0.033u + 0.096v + 0.0760u^2 + 0.0534uv + 0.094v^2 \\ &\quad + 0.013uv^2 - 0.011v^3. \end{aligned} \quad (38)$$

Fig. 4. Functions $e^{-\tau}$ (solid black), ψ_0 (solid grey), and ψ_1 (dashed grey).

This overapproximation and the polynomials are illustrated in Fig. 4. If one is satisfied with an overapproximation accuracy of $\varepsilon = e^{-1.5\pi} \approx 0.009$, then one can use this precomputed overapproximation (for the case $\theta = 1$). If it is desired to have a simpler overapproximation (with less regions and polynomials of lower degree) or an even tighter approximation with $\varepsilon < 0.009$, one can run Algorithm 1 to obtain it.

Remark 3.1. A few comments are in order:

- The reason to take the functions ϕ_l in step 3 as smooth as possible (m in C^m as large as possible) is that a lower degree K_l is needed to satisfy (34). Indeed, when $\phi_l \in C^m$ then the Fourier coefficients satisfy $k^m a_k \rightarrow 0$, $k^m b_k \rightarrow 0$ when $k \rightarrow \infty$ and thus the approximation error $|\sum_{k=0}^{K_l} [a_k \cos(k\theta\tau) + b_k \sin(k\theta\tau)] - e^{-\tau}| = |\sum_{k=K_l}^{\infty} [a_k \cos(k\theta\tau) + b_k \sin(k\theta\tau)]|$ on I_l is smaller than ε for smaller values of K_l .
- A sufficiently high degree of K_l such that (34) holds can be obtained by increasing K_l incrementally until (34) is satisfied. If one is satisfied with an overapproximation accuracy of $\varepsilon = e^{-1.5\pi}$, then the precomputed overapproximation (38) with $N = 2$ and $K_l = 3$ can be used in case $\theta = 1$.
- Instead of selecting T a priori, we can also select a maximal degree K of the approximation functions ψ_l in the sense that $K_l \leq K$ for all $l = 0, 1, \dots, N - 1$. Instead of increasing the degrees of the approximation functions ψ_l , one now can split the time interval $[0, -\ln \varepsilon]$ into smaller pieces until $|\psi_l(\cos \theta\tau, \sin \theta\tau) - e^{-\tau}| \leq \varepsilon$ for all $\tau \in I_l$ is satisfied for the fixed (low) degree K . This might lead to more regions (a larger N). This indicates that there is a trade-off between N (number of basic semialgebraic sets in the overapproximation $\mathcal{F}_{\text{approx}}$) and K (the maximal degree of the Fourier series approximation). The smaller N the higher K and vice versa. However, note that the example of the overapproximation with $N = 2$ and $K = 3$ already provides a very tight approximation of $\varepsilon = e^{-1.5\pi} \approx 0.009$ in case $\theta = 1$.
- The reason for splitting the set $\mathcal{F}_{\text{original}}$ in the $\tau = \frac{t}{m}$ direction is that the exponential function $\lambda = e^{-\tau}$ can generally not be ε -close approximated with the basis functions $\cos(\theta\tau)$ and $\sin(\theta\tau)$ in the interval $[0, -\ln \varepsilon]$ (unless ε is chosen relatively large or θ is very small and thus T can be selected larger). The additional scaling θ can be used to adjust the period of $\cos(\theta\tau)$ and $\sin(\theta\tau)$ thereby offering a trade-off between the required amount of intervals N and the order of the polynomial $y(u, v, \lambda)$ (provided the integer requirement on β_i is fulfilled). Indeed, $N = 1$ in Definition 3.1 can be obtained by choosing θ sufficiently small such that $e^{-\tau}$ can be ε -close approximated using $u = \cos(\theta\tau)$ and $v = \sin(\theta\tau)$ in the interval $[0, -\ln \varepsilon]$ for any ε . However, this implies that the polynomial order β_i (see (27)) increases due to the relation $\beta_i = \frac{\theta \beta_i}{m}$, which is undesirable from a computational point of view. On the other

hand, if θ is chosen as large as possible (while respecting the integer requirement on β_i), the order of the polynomial $y(u, v, \lambda)$ in (27) is minimal but a large amount of regions N could be required.

Using the ε -close overapproximation $\mathcal{F}_{\text{approx}}$, the conditions (32) again are a special case of Problem 2.1 with $z = q, x = (u, v, \lambda)$, $\ell = 2$, $m = 0$, $p(z, x) = 0$, $g_1(z, x) = P_5(q, u, v, \lambda)$, $g_2(z, x) = P_6(q, u, v, \lambda)$, and $\mathcal{D}_l = \mathcal{F}_l$, $l = 0, \dots, N$. However, since the polynomial positivity constraints (32) are now multivariate (meaning polynomials in more than one variable) instead of univariate, the equivalent LMI expression from Henrion et al. (2005) is not applicable. In general, checking positivity of a multivariate polynomial on a basic semialgebraic set is a hard problem, but it can often be approximated as closely as desired by a hierarchy of convex relaxations (Lasserre, 2009; Laurent, 2009). In this case, to make Problem 2.1 computationally tractable, the inequality conditions from (15) are replaced by stronger conditions in terms of primal moment and dual sums-of-squares (SOS) problems to formulate a hierarchy of upper bounds on the minimum in Problem 2.1 that converge in the limit to the real minimum. We refer the reader to Lasserre (2009) and Laurent (2009) for the conversion techniques to obtain the LMIs and further details. There exist software packages, such as GloptiPoly (Henrion & Lasserre, 2003), SOSTOOLS (Prajna, Papachristodoulou, & Parrilo, 2002) or YALMIP (Löfberg, 2004), that automatically build up a hierarchy of LMI relaxations, whose associated monotone sequence of optimal values converges to the global optimum. Numerical certificates of optimality are also available, in terms of ranks of embedded moment matrices, see Lasserre (2009) and Laurent (2009).

4. Control design procedure

To summarize the previous design setup, suppose that the d -minimal controller (2) for system (1) has been designed via the Diophantine equation (4) such that the desired closed-loop pole locations are achieved. Also suppose that more closed-loop poles are assigned than twice the number of poles of the plant. Then, according to (6) there is additional control design freedom parameterized in the form of the Youla–Kučera parameter, which can be used to shape the closed-loop time response. Time-domain constraints can be imposed using one of the proposed relaxations in Section 3, which yield the polynomial constraints in (15). Next to constraint satisfaction, (15) allows also the minimization of an objective function $p(z)$. This minimization can be exploited to obtain additional desired properties of the response in terms of the design parameters q and thus y_i , a_i and b_i . Consider the step response for example, which can be written as (18) with $p_0 = 0$ and where y_0 is the steady-state solution. Desirable properties of the unit step response are, for instance, a zero steady-state error, a small settling-time and small overshoot. These properties can be accommodated in $p(z)$ as follows

Small steady-state error: Set $p(z) = (1 - y_0)^2$ to minimize the steady-state error.

Short settling-time: Set $p(z) = a_i^2 + b_i^2$, where index i corresponds to a slow mode in (21), to minimize the contribution of this mode, which improves the settling time. Alternatively, exponentially decreasing constraints can be specified that directly impose a certain desired settling behaviour.

Overshoot minimization: In case one is interested in constraining the response by a fixed constant, e.g. constraining the overshoot, the exponential bound relaxation is not suitable. This is due to the fact that the peak values of the systems response often occur in the time interval where

the exponential upper and lower bounds are still very far from the actual signal. As opposed to the exponential bound relaxation, the multivariate polynomial relaxation from Section 3.2 is typically suited to minimize the overshoot of a step response by constraining the response (30) as $y(u, v, \lambda) \leq \gamma$ and specify $p(z) = \gamma$ to minimize the overshoot.

Of course, one can combine the above objectives in $p(z)$ using suitable weighting factors. Furthermore, the proposed relaxations enable the incorporation of the extensions that were mentioned in Section 2.2 (e.g. related to responses to disturbances) in case the poles of the Laplace transform of the corresponding signal are complex. Setting up the optimization problem (15) by including the time-domain constraints on closed-loop signals using one of the proposed relaxations and defining the objective function $p(z)$ provides a systematic manner for obtaining linear controllers with desirable properties. This design framework will be illustrated in the next section.

5. Numerical example

We start with a simple simulation example to illustrate the efficiency of the proposed design method. Consider the simple model given by

$$P(s) = \frac{y(s)}{u(s)} = \frac{1}{s+1}. \quad (39)$$

The control objective is to let y track a step reference from 0 to 1 as close as possible. Moreover, the controller (2) will be designed such that the assigned complex closed-loop poles are $p_{1,2} = -1 \pm 2j$, $p_{3,4} = -2 \pm 4j$. This is done by solving the Diophantine equation (4) leading to the d -minimal controller

$$C(s) = \frac{d_0(s)}{c_0(s)} = \frac{68}{s^3 + 5s^2 + 28s + 32}, \quad (40)$$

resulting in the closed-loop system given by the complementary sensitivity function

$$T(s) = \frac{68}{s^4 + 6s^3 + 33s^2 + 60s + 100}. \quad (41)$$

Using the Youla–Kučera parameter $q(s)$ and realizing that according to (6) we have $\deg q(s) \leq 2$, i.e., $q(s) = q_0 + q_1s + q_2s^2$, the set of allowable controllers assigning the specified closed-loop poles is parameterized as

$$C(s) = \frac{d(s)}{c(s)} = \frac{d_0(s) - a(s)q(s)}{c_0(s) + b(s)q(s)} = \frac{68 - (q_0 + (q_0 + q_1)s + (q_1 + q_2)s^2 + q_2s^3)}{s^3 + 5s^2 + 28s + 32 + (q_0 + q_1s + q_2s^2)}, \quad (42)$$

resulting in the set of closed-loop transfer functions

$$T(s) = \frac{68 - (q_0 + (q_0 + q_1)s + (q_1 + q_2)s^2 + q_2s^3)}{s^4 + 6s^3 + 33s^2 + 60s + 100}. \quad (43)$$

The Laplace transform of the time response of (43) to a step input is then parameterized as

$$y(s) = \frac{1}{s}T(s) = \frac{68 - (q_0 + (q_0 + q_1)s + (q_1 + q_2)s^2 + q_2s^3)}{s(s+1+2j)(s+1-2j)(s+2+4j)(s+2-4j)}. \quad (44)$$

The corresponding partial fractional decomposition is equal to

$$y(s) = \frac{y_0}{s} + \frac{a_1 + jb_1}{s+1+2j} + \frac{a_1 - jb_1}{s+1-2j} + \frac{a_2 + jb_2}{s+2+4j} + \frac{a_2 - jb_2}{s+2-4j} \quad (45)$$

where y_0, a_1, b_1, a_2, b_2 can be solved from the linear system of equations

$$\begin{bmatrix} 100 & 0 & 0 & 0 & 0 \\ 60 & 40 & 80 & 20 & 40 \\ 33 & 48 & 16 & 18 & 16 \\ 6 & 10 & 4 & 8 & 8 \\ 1 & 2 & 0 & 2 & 0 \end{bmatrix} \begin{bmatrix} y_0 \\ a_1 \\ b_1 \\ a_2 \\ b_2 \end{bmatrix} = \begin{bmatrix} 68 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} + \begin{bmatrix} -1 & 0 & 0 \\ -1 & -1 & 0 \\ 0 & -1 & -1 \\ 0 & 0 & -1 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} q_0 \\ q_1 \\ q_2 \end{bmatrix}, \quad (46)$$

where q_0, q_1, q_2 are the free variables in the Youla–Kučera parameter to shape the time response. The goal is to determine values of y_0, a_1, b_1, a_2, b_2 (via q_0, q_1, q_2) such that the closed-loop time response to the step input has a favourable shape. The LMI problems were modelled with YALMIP (Löfberg, 2004) and solved with SeDuMi (Sturm, 1999).

5.1. Using the exponential bound relaxation

The exponential bounds on the step response of the closed-loop system (43) are given by

$$\begin{aligned} \bar{y}_{\text{upper}}(t) &= y_0 + (2|a_1| + 2|b_1|)e^{-t} + (2|a_2| + 2|b_2|)e^{-2t}, \\ \bar{y}_{\text{lower}}(t) &= y_0 - (2|a_1| + 2|b_1|)e^{-t} - (2|a_2| + 2|b_2|)e^{-2t}, \end{aligned} \quad (47)$$

where y_0, a_1, b_1, a_2, b_2 are related to q_0, q_1, q_2 via (46). The goal of this relaxation is to determine q_0, q_1, q_2 such that

$$\begin{aligned} P_3(\lambda) &= g_u(\lambda) - y_{\text{upper}}(\lambda) \geq 0, \\ P_4(\lambda) &= y_{\text{lower}}(\lambda) - g_l(\lambda) \geq 0, \end{aligned} \quad (48)$$

for appropriately chosen *time-varying* bounds related to $g_u(\lambda)$ and $g_l(\lambda)$. Note that $\lambda = e^{-t}$ and

$$\begin{aligned} y_{\text{upper}}(\lambda) &= y_0 + (2|a_1| + 2|b_1|)\lambda + (2|a_2| + 2|b_2|)\lambda^2, \\ y_{\text{lower}}(\lambda) &= y_0 - (2|a_1| + 2|b_1|)\lambda - (2|a_2| + 2|b_2|)\lambda^2. \end{aligned} \quad (49)$$

To define the time-varying bounds, we first consider suitable upper and lower bounds on the step response that correspond to the d -minimal controller (40) (with $q = 0$). These are given by

$$\begin{aligned} g_{u_{\text{original}}}(\lambda) &= 0.68 + 1.58\lambda + 0.38\lambda^2, \\ g_{l_{\text{original}}}(\lambda) &= 0.68 - 1.58\lambda - 0.38\lambda^2, \end{aligned} \quad (50)$$

respectively. Based on these bounds, we now define tighter bounds $g_u(\lambda)$ and $g_l(\lambda)$ that are specified to be

$$\begin{aligned} g_u(\lambda) &= g_{u_{\text{original}}}(\lambda) + c_u = 1.01 + 1.58\lambda + 0.38\lambda^2 \\ g_l(\lambda) &= g_{l_{\text{original}}}(\lambda) + c_l = 0.99 - 1.58\lambda - 0.38\lambda^2 \end{aligned} \quad (51)$$

where $c_u = 0.33$ and $c_l = 0.31$ to guarantee a small steady-state error (smaller than 0.01). The dominant term in the upper and lower bound in (49) corresponds to the slow mode e^{-t} with coefficient $(2|a_1| + 2|b_1|)$. To minimize the contribution of this term and to bring the steady-state error close to zero, we specify the objective function according to Section 4 as

$$p(q_0, q_1, q_2) = 10(1 - y_0)^2 + 2(a_1^2 + b_1^2), \quad (52)$$

where y_0, a_1 and b_1 depend on q_0, q_1, q_2 as in (46). This results in the optimization problem

$$\begin{aligned} \min_{q_0, q_1, q_2} & p(q_0, q_1, q_2) \\ \text{s.t.} & (46) \\ & (48) \quad \forall \lambda \in [0, 1]. \end{aligned} \quad (53)$$

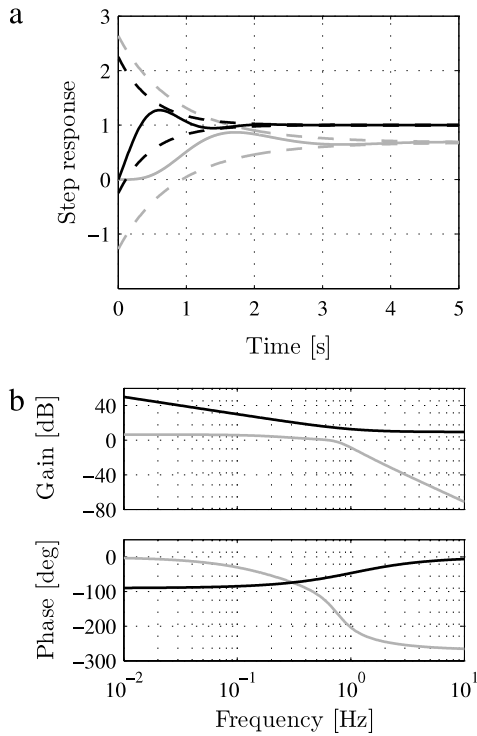

Fig. 5. Results of exponential bound relaxation. (a) New (solid black) and original (solid grey) step responses, original bounds (dashed grey), and new bounds (dashed black), (b) bode diagrams of the original (grey) and the new (black) controller.

The Youla–Kučera parameter resulting from the minimization problem (53) is

$$q(s) = -32.0 - 23.0s - 3.0s^2, \quad (54)$$

which yields the controller and closed-loop

$$C(s) = \frac{3s^3 + 26s^2 + 55s + 100}{s^3 + 2s^2 + 5s}, \quad (55)$$

$$T(s) = \frac{3s^3 + 26s^2 + 55s + 100}{s^4 + 6s^3 + 33s^2 + 60s + 100}, \quad (56)$$

together with the new bounds

$$\begin{aligned} g_{u_{\text{new}}}(t) &= 1.00 + 1.25e^{-2t}, \\ g_{l_{\text{new}}}(t) &= 1.00 - 1.25e^{-2t}. \end{aligned} \quad (57)$$

This shows that the steady-state error is zero and the contribution of the slow mode has been completely eliminated. The step responses together with their bounds of the original closed-loop system (41) and of the new, optimized closed-loop system (56) are depicted in Fig. 5(a), while the Bode diagrams of the original controller (40) and the new controller (55) are shown in Fig. 5(b). From Fig. 5(a) it is obvious that the step response of the designed closed-loop system satisfies the specified bounds and additionally results in zero steady-state tracking error. Upon examination of Fig. 5(b) this can be explained by the fact that controller (55) exhibits an overall higher gain and hence results in a higher bandwidth of the closed-loop system resulting in a faster response, while it also implements integrating action providing the steady-state accuracy. Although there is some conservatism introduced by the fact that upper and lower bounds are used, this example demonstrates that a significant increase of the performance can be obtained using this method.

Remark 5.1. In this example the ability of the method to minimize the contribution of the slow mode using an additional objective

function $p(z)$ in Problem 2.1 was demonstrated. Because of the specific objective function (52) the slow mode was completely cancelled within the controller. Therefore, for this specific example another way to arrive at controller (55) is to specify only two closed-loop poles $p_{3,4} = -2 \pm 4j$ (without $p_{1,2} = -1 \pm 2j$), resulting in $C(s) = \frac{3s+20}{s}$, which indeed is the minimal form of (55). Interestingly, the optimization problem results in this controller in an automated and systematic manner.

5.2. Using the multivariate polynomial relaxation

In this section, the multivariate polynomial relaxation from Section 3.2 is used to obtain suitable values of q_0, q_1, q_2 to improve the step response of closed-loop system (43). We have that $m = 1, n_r = 0, n_c = 2, \bar{\alpha}_1 = -1, \bar{\alpha}_2 = -2, \bar{\beta}_1 = 2$ and $\bar{\beta}_2 = 4$. Let $\theta = 1$ such that $u = \cos(\tau)$ and $v = \sin(\tau)$ so that (27) yields

$$\begin{aligned} y(t) &= ((a_1 + jb_1)(u + jv)^2 + (a_1 - jb_1)(u + jv)^2)\lambda \\ &\quad + ((a_2 + jb_2)(u + jv)^4 + (a_2 - jb_2)(u + jv)^4)\lambda^2 \\ &= (2a_1(u^2 - v^2) + 2b_1 2uv)\lambda \\ &\quad + (2a_2(u^4 + v^4 - 6u^2v^2) + 2b_1(4uv^3 - 4uv^3))\lambda^2. \end{aligned} \quad (58)$$

As a consequence, for this example we obtain

$$\begin{aligned} w_1(u, v) &= u^2 - v^2, & r_1(u, v) &= 2uv \\ w_2(u, v) &= u^4 + v^4 - 6u^2v^2, & r_2(u, v) &= 4uv^3 - 4uv^3 \end{aligned} \quad (59)$$

yielding the time response

$$\begin{aligned} y(u, v, \lambda) &= y_0 + (2a_1(u^2 - v^2) + 4b_1uv)\lambda \\ &\quad + (2a_2(u^4 + v^4 - 6u^2v^2) + 8b_2(vu^3 - uv^3))\lambda^2, \end{aligned} \quad (60)$$

which is a multivariate polynomial with 3 independent variables (u, v, λ) and three decision variables (q_0, q_1, q_2) . Note that $(u, v, \lambda) \in \mathcal{F}_{\text{original}}$. Since $\mathcal{F}_{\text{original}}$ is not the finite union of a basic semialgebraic set, we can use Algorithm 1 or use the precomputed overapproximation in Section 3.2 to obtain an ε -close overapproximation $\mathcal{F}_{\text{approx}}$ of $\mathcal{F}_{\text{original}}$. We use here the precomputed overapproximation $\mathcal{F}_{\text{approx}}$ with $\varepsilon = e^{-1.5\pi} \approx 0.009$. In accordance with Section 4, we formulate the problem as to find q such that the overshoot γ is small and that the steady-state error of the step response is minimized. Therefore, the problem is posed as

$$\begin{aligned} \min_{q_0, q_1, q_2} & 10(1 - y_0)^2 + \gamma \\ \text{s.t.} & (46) \\ & \gamma - y(u, v, \lambda) \geq 0 \quad \forall (u, v, \lambda) \in \mathcal{F}_{\text{approx}}. \end{aligned} \quad (61)$$

Rewriting this optimization problem gives

$$\begin{aligned} \min_{q_0, q_1, q_2} & 10(1 - y_0)^2 + \gamma \\ \text{s.t.} & (46) \\ & \gamma - y(u, v, \lambda) \geq 0 \quad \forall (u, v, \lambda) \in \mathcal{F}_0 \\ & \gamma - y(u, v, \lambda) \geq 0 \quad \forall (u, v, \lambda) \in \mathcal{F}_1 \\ & \gamma - y(u, v, \lambda) \geq 0 \quad \forall (u, v, \lambda) \in \mathcal{F}_2, \end{aligned} \quad (62)$$

with $\mathcal{F}_{0,1}$ as in (35) and \mathcal{F}_2 as in (33). This optimization problem is then solved with a hierarchy of LMI relaxations, as explained at the end of Section 3.2. The size of the resulting LMI problem depends on the order of the relaxation, and this can be used as a tuning knob to adjust the trade-off between the desired accuracy and the computational complexity, see Section 2. Although it is a priori not clear what is the order of the relaxation to arrive at the global minimum of γ , a heuristic method is to increase the order until not much improvement in the relaxed optimum $\tilde{\gamma}$ is observed anymore or until one is satisfied with the obtained value

Table 1
Upper bound $\tilde{\gamma}$ for various orders of LMI relaxation.

	Order of LMI relaxation					
	1	2	3	4	5	10
$\tilde{\gamma}$	297.170	1.235	1.235	1.0718	1.0718	1.0718

Fig. 6. New (black) and original (grey) step responses.

of $\tilde{\gamma}$. The obtained minimum values of $\tilde{\gamma}$ for various orders of relaxation are given in Table 1. We used this heuristic approach for illustration purposes only. It is recommended to use the more systematic approach that is implemented in GloptiPoly (Henrion & Lasserre, 2003) to arrive at the global minimum, and certify it numerically. Based on the figures in this table we expect that the global minimum of γ is equal to 1.0718, representing an overshoot of 7.18%. The corresponding Youla–Kučera parameter is given by

$$q(s) = -32.0 - 17.0607s - 3.0227s^2, \quad (63)$$

which yields the controller

$$C(s) = \frac{3.0s^3 + 20.0s^2 + 49s + 100}{s^3 + 2.0s^2 + 10.9s}. \quad (64)$$

The step responses of both the original closed loop with the d -minimal controller (40) and of the closed loop with controller (64) are depicted in Fig. 6, which shows a significant improvement as expected. The maximum of the step response $y(t)$ equals 1.0714 (i.e., 7.14% overshoot), which indeed is ε -close to $\tilde{\gamma} = 1.0718$.

This example showed that after controller design by pole placement it is possible to shape the transient time response of the system by assigning zeros to the closed-loop system through a suitable extension of the controller under pole invariance.

6. Conclusions

In this paper we provided a generally applicable design framework to obtain linear controllers for linear systems subject to time-domain constraints. In order to arrive at this design framework we extended recent results in Henrion et al. (2005) that applied only in case of *real* closed-loop poles and external signals (e.g. references or disturbances) having Laplace transforms with *real* poles. The design method is based on synthesizing linear controller via a closed-loop pole placement method in which the additional design freedom in terms of the Youla–Kučera parameter is used to satisfy time-domain constraints on the closed-loop signals based on sum-of-square techniques. In order to extend the method to the practically relevant case where both inputs and closed-loop systems with complex conjugate poles are allowed, we proposed two relaxations.

The first relaxation, called the exponential bound relaxation, exploited exponential upper and lower bounds on the response to

any Laplace transformable input. Although this gives rise to potential conservatism, an example showed that by prescribing polynomial time-domain bounds, the system's performance to a step input can be improved with respect to the settling-time and the steady-state error. The second relaxation, the multivariate polynomial relaxation, removed the potential conservatism completely as we formally proved that it can approximate the original problem with arbitrary accuracy. Using these relaxations, we indicated how a polynomial optimization problem could be set up, in which next to constraint satisfaction, we could also optimize certain important closed-loop properties such as overshoot, settling-time and steady-state error. The resulting optimization problem can be solved using sum-of-squares and convex programming methods. As a consequence, the provided design framework is systematic in nature, as was also illustrated using a numerical example.

W.H.T.M. Aangenent received the M.Sc. degree (cum laude) in Mechanical Engineering from Eindhoven University of Technology (TU/e), Eindhoven, The Netherlands. In 2008 he received the Ph.D. degree from Eindhoven University of Technology on the subject of Nonlinear control of linear motion systems. Currently, he is working at ASML Research Mechatronics, Veldhoven, The Netherlands.

W.P.M.H. Heemels received the M.Sc. in mathematics (with the highest distinction) and the Ph.D. degrees (cum laude) from the Eindhoven University of Technology (TU/e), Eindhoven, the Netherlands, in 1995 and 1999, respectively. From 2000 to 2004, he was with the Electrical Engineering Department, TU/e, as an Assistant Professor, and from 2004 to 2006 with the Embedded Systems Institute (ESI) as a Research Fellow. Since 2006, he has been with the Department of Mechanical Engineering, TU/e, where he is currently a Full Professor in the Hybrid and Networked Systems Group. He held visiting research positions at the Swiss Federal Institute of Technology (ETH), Zurich, Switzerland (2001) and at the University of California at Santa Barbara (2008). In 2004, he was also at the Research and Development laboratory, Océ, Venlo, the Netherlands. His current research interests include hybrid and nonsmooth dynamical systems, networked control systems and constrained systems including model predictive control. Dr. Heemels is an Associate Editor for the journals *Automatica* and *Nonlinear*

Analysis: Hybrid Systems and will serve as the General Chair of the 4th IFAC Conference on Analysis and Design of Hybrid Systems 2012 in Eindhoven, The Netherlands.

M.J.G. van de Molengraft received the M.Sc. degree (cum laude) in Mechanical Engineering from Eindhoven University of Technology, Eindhoven, The Netherlands, in 1986. From 1986 until 1990 he was a research assistant at Eindhoven University of Technology. In 1990 he received the Ph.D. degree from Eindhoven University of Technology on the subject of Identification of Mechanical Systems for Control. In 1991 he fulfilled his military service. Since 1992 he is a staff member of the Control Systems Technology group of the Mechanical Engineering Department of Eindhoven University of Technology (assistant professor from 1992 to 2008, associate professor from 2008). In 2005, he founded the Tech United Robocup team (vice world champion in 2008, 2009 and 2010). Since 2008, he is an associate editor of *IFAC Mechatronics*.

D. Henrion received the Engineer's and Masters' Degrees with specialization in control from the National Institute of Applied Sciences (INSA), Toulouse, France, in 1994. He received a Ph.D. Degree from the Academy of Sciences of the Czech Republic in 1998, a Ph.D. degree from INSA Toulouse in 1999, a French Habilitation Degree from the University of Toulouse in 2007, and a Czech Habilitation Degree from the Czech Technical University in Prague in 2008. Since 2000, he has been a CNRS researcher at the Laboratory of Analysis and Architecture of Systems in Toulouse, as well as an associate professor at Faculty of Electrical Engineering of the Czech Technical University in Prague. In 2004 he was awarded the Bronze Medal from CNRS. From 2004 to 2010 he has chaired the IEEE Technical Committee on Computer-Aided Control System Design. He has been in the editorial boards of *IFAC Automatica* (2003–2009), *Slovak Journal of Electrical Engineering* (2004–2010), *IEEE Transactions on Automatic Control* (2005–2008), *European Journal of control* (2005–2008), *Kybernetika* (since 2008) and *Mathematics of Control, Systems and Signals* (since 2011). He is interested in polynomial optimization for systems control, focusing on the development of constructive tools for addressing mathematical problems arising from systems control theory.

M. Steinbuch (1960) received the M.Sc. degree (cum laude) in Mechanical Engineering from Delft University of Technology, Delft, The Netherlands, in 1984. From 1984 until 1987 he was a research assistant at Delft University of Technology and KEMA, Arnhem, The Netherlands. In 1989 he received the Ph.D. degree from Delft University of Technology. From 1987 to 1998 he was with Philips Research Labs., Eindhoven as a Member of the Scientific Staff. From 1998 to 1999 he was manager of the Dynamics and Control group at Philips Center for Manufacturing Technology. Since 1999 he is full professor in Systems and Control, and head of the Control Systems Technology group of the Mechanical Engineering Department of Eindhoven University of Technology. He was an Associate Editor of the *IEEE Transactions on Control Systems Technology*, of *IFAC Control Engineering Practice*, and of *IEEE Control Systems Magazine*. He was Editor-at-Large of the *European Journal of Control*. Currently, he is Editor-in-Chief of *IFAC Mechatronics* and Associate Editor of *Int. Journal of Powertrains*. He is program leader of the TU/e Master of Science Automotive Technology, member of the board of HTAS and HTAC, member of the Formule E team, Chairman of the Stichting Techniekpromotie, member of the Advisory Board of the DSPE, of The Institute, and co-founder of MI-Partners. Since July 2006 he is also Scientific Director of the Centre of Competence High Tech Systems of the Federation of Dutch Technical Universities. In 2003, 2005 and 2008 he obtained the 'Best-Teacher' award of the Department of Mechanical Engineering, TU/e. His research interests are modelling, design and control of motion systems, robotics, automotive powertrains and control of fusion plasmas.
